## Affecting Factors:

This builds on the factors presented in Chapter 4.

Steric hindrance greatly slows S $_N$ 2 by shielding  $^{\delta+}\text{C}$  from nucleophilic attack. E $_2$  may also be slowed if bulky bases are used.

**Carbocation stability** increases rate of  $E_1$  and  $S_N$ 1 by decreasing  $E_a$  leading to the carbocation intermediate. Carbocations can be stabilized by inductive donation of s-orbital  $e^-$  by adjacent R-groups, or by resonance delocalization to spread the positive charge on more atoms.

Nucleophilicity chooses  $S_N 2$  over  $S_N 1$ , while basicity is important in  $E_2$ . The greater the charge

density (-ve), the stronger the nucleophile, but in polar protic solvents, nucleophilicity decreases in the order HS $^->HO^-$  and I $^->Br^->CI^->F^-$ . as the smaller anions are more strongly solvated (not the case in polar aprotic solvents). Nucleophilicity parallels basicity, except where a bulky base is too bulky to be a good Nu $^-$ . Note that nucleophilicity measures how good a lone pair is in adding to an electrophilic centre (like carbon), while basicity is how good that species is in donating a lone pair to H+ and hence deprotonating another species.

The stability of the **leaving group** increases the rate of  $S_N 2$ , and favours  $S_N 1$  over  $E_1$ . The greater the ability to stabilize the negative charge, i.e. the larger the size (more impt.) or the more electronegative the group, the better it is as a leaving group. Good leaving groups:  $X^-$ ,  $H_2O$ . Poor leaving groups:  $OH^-$ ,  $F^-$ ,  $NH_2^-$ , ...

**Polar protic solvents** can solvate both cations and anions, including via hydrogen bonds. Polar aprotic ones lack  $^{S+}$ H to solvate anions, not forming solvent cages around Nu $^-$ , hence increasing the charge density and reactivity of the Nu $^-$ , increasing rate of S $_N$ 2 reactions. Generally, polar solvents (stabilizes cations) are sufficient for S $_N$ 1/E $_1$ .

**Temperature**, if increased, favours,  $E_1$  and  $E_2$  as entropy increases the elimination reactions (more molecules produced).

**Neighbouring groups** may participate in and accelerate  $S_N2$ , the rule being that intramolecular reactions are faster than intermolecular reactions. This "double  $S_N2$ " leads to retention of configuration instead of inversion of configuration as with a single  $S_N2$ .

Multiple products may be possible for  $E_2$ , favouring the more substituted products. It is first necessary to consider the possibility of  $E_2$ , which depends on whether the H and leaving group are anti-periplanar/trans-diaxial. It is a stereochemical requirement of  $E_2$  reactions for the H eliminated and the leaving group to be anti-periplanar (i.e. on opposite sides). The anti-periplanar elimination occurs even if the product does not follow Sayzeff's Law. The full explanation for the anti-periplanar requirement requires an understanding of MO theory which we should not concern ourselves with at this stage (for the curious: the reason is electron donation into the anti-bonding orbital of the C-leaving group).

Choosing the right reaction conditions often allows selection of the desired products.
